Chapter 1

Acting under uncertainty

1.1 Basic probability notation

Every agent based on **decision theory** needs a formal language to use and represent probabilistic informations. Typically AI needs a more suited and consistent approach than the traditional probability theory. This section includes all the necessary definitions and examples to understand the subsequent arguments in depth.

Definition

The set of all possible worlds is called the **sample space**, denoted Ω . Any subset $A \subseteq \Omega$ is an **event**. Any element $\omega \in \Omega$ is called **sample point**.

Definition

A **probability space** is a sample space with an assignment $P(\omega)$ for every $\omega \in \Omega$ where:

- $0 \le P(\omega) \le 1$
- $\sum P(w) = 1$ for every $\omega \in \Omega$

Definition

A **random variable** is a function from sample points to some range, e.g., the reals or Booleans.

e.g.
$$Odd(1) = true$$

Definition

P induces a **probability distribution** for any random variable X:

$$P(X = x_i) = \sum_{\omega: X(\omega) = x_i} P(\omega)$$

A probability distribution gives values for all possible assignment.

Definition

Prior or **unconditional probabilities** of propositions correspond to belief prior to arrival of any new evidence.

e.g.
$$P(Cavity = True) = 0.1$$

Definition

The **Joint Probability Distribution** for a set of random variables gives the probability of every sample point on those random variables.

e.g. $P(Weather, Cavity) = a \ 2 \times 4 \ matrix \ of \ values$:

Weather =	sunny	rain	cloudy	snow
Cavity = True	0.144	0.02	0.016	0.02
Cavity = False	0.576	0.08	0.064	0.08

Every question about a certain domain can be answered by the joint distribution because every event is a sum of sample points.

Definition

A function $p: R \to R$ is a **probability density function** (**pdf**) for X if it is a nonnegative integrable function s.t.

$$\int_{Val(X)} p(x)dx = 1$$

Definition

Conditional or posterior probabilities P(X|Evidence) represent a more informed distribution in the light of new evidence.

e.g.
$$P(cavity|toothache) = 0.8$$

It does not mean "if I have toothache then there is 80% of chance that there is also a cavity", instead the evidence mean "given toothache evidence is all I know".

The typically definition of conditional or posterior probability is:

$$P(a|b) = \frac{P(a \land b)}{P(b)}$$
 if $P(b) \neq 0$

Otherwise, numerator can be written by the **product rule**:

$$P(a \wedge b) = P(a|b)P(b) = P(b|a)P(a)$$

The product rule at the same time is applied to whole distributions, not only for single values as done previously.

$$P(Weather, Cavity) = P(Weather|Cavity)P(Cavity)$$

1.2 Inference using full join distribution

This paragraph describes a new method to retrieve informations from data, named **probabilistic inference**. It allows the computation of conditional probabilities for query propositions by given evidence. Starting from an example is defined the full **joint distribution** as the knowledge base from which answers to all questions.

Example

e.g. (Toothache, Cavity, Catch) is just a domain consisting of three Boolean variables. Catch condition occurs when the dentist's steel probe catches in the tooth. Based on the domain, the full joint distribution seems like this:

	toothache		$\neg toothache$	
	catch	$\neg catch$	catch	$\neg catch$
cavity	0.108	0.012	0.072	0.008
$\neg cavity$	0.016	0.064	0.144	0.576

The equation

$$P(\phi) = \sum_{\omega:\omega\models\phi} P(\omega)$$

 $P(\phi) = \sum_{\omega:\omega \models \phi} P(\omega)$ gives a direct way to calculate probabilities of any assertions, summing up all the possible worlds that satisfy the original proposition.

e.g.
$$P(toothache) = 0.108 + 0.012 + 0.016 + 0.064 = 0.2$$

e.g. $P(cavity \lor toothache) = 0.108 + 0.012 + 0.072 + 0.008 + 0.016 + 0.064 = 0.28$

It's also possible compute conditional probabilities:

e.g.
$$P(\neg cavity | toothache) = \frac{P(\neg cavity \land toothache)}{P(toothache)} = \frac{0.016 + 0.064}{0.2} = 0.4$$

Notice that in this calculation the term P(toothache) remains constant, no matter which value of Cavity is computed. In fact, it can be viewed as a **normalization constant** (α) for the whole distribution P(Cavity|toothache), ensuring that the positive and negative case sum up to one, as the second probability axiom requires.

```
\mathbf{P}(Cavity|toothache) = \alpha \mathbf{P}(Cavity, toothache)
= \alpha [\mathbf{P}(Cavity, toothache, catch) + \mathbf{P}(Cavity, toothache, \neg catch)]
= \alpha [\langle 0.108, 0.016 \rangle + \langle 0.012, 0.064 \rangle]
= \alpha \langle 0.12, 0.08 \rangle = \langle 0.6, 0.4 \rangle
```

Definition

The first probability calculated P(toothache) is called **marginalization**, or more simply **summing out**, because it sums up the probabilities for each possible value of the other variables.

Definition

The second one $P(\neg cavity|toothache)$ is named **conditioning**, a variant of marginalization that involves conditional probabilities instead of joint probabilities.

Definition

From the example, it's possible to extract a general inference procedure. Let \mathbf{Y} be the query variables. Let \mathbf{E} be the list of evidence variables, let \mathbf{e} be the list of observed values for them, and let \mathbf{H} be the unobserved variables. The **probability query** $\mathbf{P}(Y|\mathbf{e})$ defines the posterior joint distribution of a set of **query variables** \mathbf{Y} given specific values \mathbf{e} for some **evidence variables** \mathbf{E} :

$$\mathbf{P}(Y|e) = \alpha \mathbf{P}(Y, E = e) = \alpha \sum_{h} \mathbf{P}(Y, E = e, H = h)$$

The full join distribution can answer probabilistic queries for discrete variables, but only for small domains. It does not scale well: for a domain described by n Boolean variables, it requires an input table of size $O(2^n)$ and takes $O(2^n)$ time to process a question. The full joint distribution in tabular form is just not a practical tool for building reasoning systems.
